The first and the second edition of Applied Tribology Bearing Design and Lubrication were published in 2001 and 2008, respectively. Both books enjoy a five star ranking on the Amazon book list. The new edition follows the same style and structure as the two previous ones. The book starts with general description of the tribological concepts such as friction, wear, lubricants and lubrication, surface texture and bearing materials. The text then follows with detailed explanation of the lubrication regimes and the corresponding bearing designs. Two chapters that follow contain information on bearing selection and operating limits, very useful for practicing engineers. The book finishes with a chapter on seal fundamentals. In comparison to the second edition, this new version is much improved. The text has been updated, some of the chapters significantly extended, additional references included, and occasional errors removed. Throughout the text several new numerical examples, supporting the problems discussed, have also been added.

Substantial new sections have been included in several chapters. In particular, Chapter 3 has been thoroughly revised and enhanced by new segments on contact between surfaces, friction and wear phenomena, classification of wear, failure modes and wear maps. Chapter 6 has been supplemented by a discussion on optimizing a finite Rayleigh step bearing. In Chapter 7 a useful section on the maximum bearing temperature calculations, based on the thermohydrodynamic analysis, has been included. In Chapter 8 sections on tilted pad journal bearings, maximum bearing temperature and whirl instability have been added. Updated Chapter 9 now contains a discussion on the combined squeeze and rotational motion and vertical bearing configuration, commonly found in industrial applications. Chapter 15 has been updated by including discussions on mixed film lubrication, lubricant starvation, models of non-Newtonian behavior of lubricants, greases and solid lubricants. Chapter 16, dedicated to seal foundations, contains now a discussion on thermal effects in mechanical face seals and ways of reducing the surface temperature.

From the viewpoint of the reader, a great advantage of this book is that complex lubrication mechanisms and their practical applications in bearings are presented in an easily accessible form. Clear and straightforward style makes this book a highly attractive text for both undergraduate and postgraduate engineering students. The book is not only a good textbook but also a very useful reference. Thus it is highly recommended for undergraduate and postgraduate students studying tribology and machine design and as well as a solid reference for mechanical
engineers. It is expected that this new edition, as its two predecessors, would be equally popular and continue to maintain its five star ranking on the engineering book list.

Preface

Third Edition

The Second Edition of the Applied Tribology was published nearly a decade ago. Since then, the book has been adopted for courses in many universities as has served as the basis for many short courses and lectures in industries. With great appreciation to many positive comments received, the Third Edition has expanded chapters on micro-contact of surface asperities, friction and wear, thermal effect, and elastohydrodynamic and mixed lubrication. Nearly all chapters have been revised with expanded sections, updates with an emphasis on new research and development, and many additional references. As in the previous editions, we strive to maintain a balance between application and theory. Each chapter contains numerous example problems to illustrate how different concepts can be applied in practice. We hope that this book can serve the need for a single resource for a senior elective or a graduate-level course in tribology and a reference book for practicing engineers in the industry.

This edition would not have been possible without the inspiring research and assistance of numerous colleagues and former students associated with the Center for Rotating Machinery at Louisiana State University. In particular, we gratefully acknowledge the feedback by Drs. J. Jang, S. Akbarzadeh, X. Lu, J. Wang, W. Jun, Z. Luan, M. Mansouri, K. ElKholy, Z. Peng, Y. Qiu, M. Amiri, M. Naderi, A. Beheshti, M. Masjedi, J. Takabi, M. Fesanghary, A. Aghdam, A. Kahirdeh, and A., Mesgarnejad, A., N. Xiao, A. Rezasolatani, and C. Shen.

Michael M. Khonsari
E. Richard Booser
Tribology is a diverse field of science involving lubrication, friction, and wear. In addition to covering tribology as involved in bearings, the same basic principles are also demonstrated here for other machine elements such as piston rings, magnetic disk drives, viscous pumps, seals, hydraulic lifts, and wet clutches.

In this second edition of *Applied Tribology* all the chapters were updated to reflect recent developments in the field. In addition, this edition contains two new chapters: one on the fundamentals of seals and the other on monitoring machine behavior and lubricants, as well as bearing failure analysis. These topics are of considerable interest to the industry practitioners as well as students and should satisfy the needs of the tribology community at large.

Computer solutions for basic fluid film and energy relations from the first edition have been extended to seal performance. New developments in foil bearings are reviewed. For ball and roller bearings, conditions enabling infinite fatigue life are covered along with new ASME and bearing company life and friction factors.

Properties of both mineral and synthetic oils and greases are supplemented by an update on the greatly extended service life with new Group II and Group III severely hydrocracked mineral oils. Similar property and performance factors are given for full-film bearing alloys, for dry and partially lubricated bearings, and for fatigue-resistant materials for rolling element bearings. Gas properties and performance relations are also covered in a chapter on gas bearing applications for high-speed machines and for flying heads in computer read–write units operating in the nanotribology range.

Problems at the close of each chapter aid in adapting the book as a text for university and industrial courses. Many of these problems provide guidelines for solution of current design and application questions. Comprehensive lists of references have been brought up to date with 145 new entries for use in pursuing subjects to greater depth.

Both SI and traditional British inch-pound-second units are employed. Units in most common use are generally chosen for each section: international SI units for ball and roller bearing dimensions and for scientific and aerospace illustrations, traditional British units for oil-film bearings in industrial machinery. Many analyses are cast in dimensionless terms, enabling use of either system of units. Conversion factors are tabulated in two appendices, and guidelines for applying either system of units are given throughout the book.

The authors are indebted to past coworkers and students for their participation in developing topics and concepts presented in this book. Comprehensive background information has been
assembled by the authors from their combined 80 years of laboratory, industrial, teaching, and consulting experience. Much of this background has been drawn from well over 250 technical publications, most of them in archival literature. Theses and dissertation projects at Ohio State University, the University of Pittsburgh, Southern Illinois University, Louisiana State University; and the Pennsylvania State University; numerous industrial projects at the Center for Rotating Machinery at Louisiana State University; four tribology handbooks organized and edited for the Society of Tribologists and Lubrication Engineers; and a 1957 book *Bearing Design and Application* coauthored with D. F. Wilcock.

This book is intended (1) for academic use in a one-semester senior engineering elective course, (2) for a graduate-level course in engineering tribology and (3) as a reference book for practicing engineers and machine designers. It is hoped that these uses will provide paths for effectively designing, applying, and lubricating bearings and other machine elements while taking advantage of concepts in tribology—the developing science of friction, wear, and lubrication.

Part I

General Considerations
1

Tribology – Friction, Wear, and Lubrication

*Tribology* is a relatively new term derived from the Greek word *tribos* for ‘rubbing’. It is now universally applied to the emerging science of friction, wear, and lubrication involved at moving contacts. In its broad scope, it involves mechanical, chemical, and material technology. Usual tasks in tribology are reduction of friction and wear to conserve energy, enabling faster and more precise motions, increased productivity, and reduced maintenance.

Tribology was formally identified as an important and unified technical field in a report issued by a committee of the British Ministry of State for Education and Science chaired by Peter Jost (1966). The report concluded that huge savings would be possible in the United Kingdom by fully utilizing improved design and lubrication procedures. The unified approach to this field filled an existing void, and the American Society of Mechanical Engineers (ASME) then adopted the term for its Tribology Division in 1983 and the American Society of Lubrication Engineers revised its name to the Society of Tribologists and Lubrication Engineers in 1985.

Fundamental interest in tribology now exists for lubricant formulation, industrial operations, aerospace and transportation equipment, material shaping and machining, computers and electronic devices, power generation, and almost all phases of life where motion is encountered. This text focuses primarily on tribology of bearings and a number of related applications. Fundamentals are applied in such a way as to allow application of the principles of tribology to a variety of other machine elements.

1.1 History of Tribology

Many of the advances in tribology and bearing technology evolved over years, decades, or even centuries to meet the needs of new machinery. The Industrial Revolution, with its increase in rotational speeds beyond those of the windmill and cart axle, brought full hydrodynamic lubrication into normal use. Theory and technical understanding commonly followed actual machinery applications. In many cases, this understanding of technical details played a
vital role in continued improvements in bearing design, lubricants, and surface treatments for industrial machinery, aerospace units, transportation equipment, magnetic storage, and micro-electromechanical devices.

A few historical stepping stones related to the primary subjects covered in this textbook will now be reviewed. Many of these events are covered in more detail in the references presented at the end of this chapter. The interested reader is referred to Dowson (1998) for an excellent review of the history of tribology.

Friction

The notebooks of the famed engineer and artist Leonardo da Vinci revealed his postulation in 1508 of the concept of a characteristic coefficient of friction as the ratio of friction force to normal load. The French physicist Guillaume Amontons (1699) again established the significance of a coefficient of friction, which was independent of the apparent area of contact. The French physicist C.A. Coulomb (1785) further distinguished between static friction and kinetic friction, which was independent of velocity. Mechanisms for reduction of friction and wear with soft coatings and adherent molecular and lubricant surface layers were elucidated by Bowden and Tabor (1950).

Wear

This subject has proven to be quite complex, and generalizations are still elusive. Hundreds of empirical equations have been generated for specific materials and conditions. The most useful one appears to be that of Archard (1953), which enables a generalized dimensionless wear coefficient \( k = \frac{VH}{Wd} \) to relate wear volume \( V \) to sliding distance \( d \), normal load \( W \), and indentation hardness \( H \) of the wearing material (see Chapter 3). This equation best describes the nature of the so-called adhesive wear. Other types of wear such as abrasive and corrosive are also described in Chapter 3.

Bearing Materials

For many centuries wood, stone, leather, iron, and copper were common bearing materials. Almost all engineering materials have now been employed in the continuing search for the best bearing material (see Chapter 4). In an early consideration of improved materials, Robert Hooke (1684) suggested steel shafts and bell-metal bushes as preferable to wood shod with iron for wheel bearings (Bhushan, 1999). High-lead and high-tin alloys patented in the United States in 1839 by Isaac Babbitt are unsurpassed for a wide range of industrial, automotive, and railway applications. An early German study of railway journal bearings by F.A. von Pauli (1849) established a composition similar to that of Babbitt (91% tin, 6% copper, and 3% zinc) as the best of 13 bearing metals (Cameron, 1966; 1976).

Suitably hard, fatigue-resistant rolling element bearing materials were achieved with modification of tool steel in Europe about 1900. This led to the development of AISI 52100 steel and its derivatives, which have since been used for all types of commercial and automotive rolling bearings.
Porous metal bearings were introduced in the 1920s. Plastics and composites involving polymers compounded with a wide variety of solid filler materials have found wide use, gaining their greatest impetus with the invention of nylon and polytetrafluoroethylene (PTFE) during World War II. The search continues, with ceramics among the materials being developed for high-temperature capability in aircraft engines and for high-speed rolling element bearings.

**Lubricants**

Tallow was used to lubricate chariot wheels before 1400 BC. Although vegetable oils and greases were used later, significant advances in the development of lubricants occurred only after the founding of the modern petroleum industry with the opening of the Drake well in Titusville, Pennsylvania, in 1859. Lubricant production reached 9500 m³/yr (2 500 000 gal/yr) in the following 20 years; worldwide production now exceeds 1000 times that volume at 1 million barrels/day. Petroleum lubricants still constitute well over 95% of total oil and grease production volume.

The past 20 years have seen a dramatic world-wide growth in hydrocracking petroleum oils to give Grade II and III lubricants with a three-fold life upgrade in many automotive and industrial applications (see Chapter 2).

Polymerized olefins were the first synthetic oils to be produced. This occurred in 1929 in an effort to improve on properties of petroleum oils. Interest in ester lubricants dates from 1937 in Germany, and their production and use expanded rapidly during and following World War II to meet military needs and for use in the newly developed jet aircraft engines. A broad range of other synthetic lubricants came into production during that same period for wide-temperature use, fire resistance, and other uses geared to a range of unique properties (see Chapter 2). Current production of synthetics approaches 100 million gal/yr, with nearly half being polyalphaolefin synthetic hydrocarbons.

Development of chemical additives to upgrade the properties and extend the lives of lubricating oils began about 1920. Commercial use has proceeded since about 1930 in step with increasing demands in automobiles, jet engines and other aerospace units, and high-speed and high-pressure hydraulic equipment (see Chapter 2).

Air, water, gasoline, solvents, refrigerant gases, air, and various fluids being processed in individual machines began to find use as ‘lubricants’ on a broadening scale in fluid-film bearings in the second half of the 1900s as improved designs and mating materials were developed on a customized basis.

**Fluid-Film Bearings**

The first studies of a shaft and bearing running under full hydrodynamic conditions were performed by F.A. von Pauli in 1849 and by G.A. Hirn in 1854 (see Cameron, 1966). In 1883 the celebrated Russian Nikilay Petroff concluded that friction in fluid-film bearings was a hydrodynamic phenomenon. His resulting power loss equation has continued to provide a foundation in this field (see Chapter 5).

Beauchamp Tower in 1883 found hydrodynamic lubrication experimentally and reported the generation of pressure in the oil film of a journal bearing. In considering Tower’s findings,
Osborne Reynolds (both working under stimulus from the British Institution of Mechanical Engineers) in 1886 developed a mathematical expression for this pressure buildup that has become the foundation of hydrodynamic analysis of bearing performance (see especially Chapters 5 and 6). Thrust and journal bearing design guides are covered in Chapters 7 and 8, respectively.

Solution of the Reynolds equation was difficult, and Arnold Sommerfeld in 1904 developed a direct integration that enabled ‘infinite length’ analyses. Alastair Cameron and Mrs W.L. Wood in 1949 made an extremely useful solution to the Reynolds equation for finite-length journal bearings by a relaxation procedure carried out with a mechanical desktop calculator. Initiated in 1958 by Oscar Pinkus and by Albert Raimondi and John Boyd, digital computer analysis of journal bearing performance has come into widespread use for obtaining numerical solutions of the Reynolds equation. Recent advances have focused on solving the Reynolds equation with consideration of cavitation. Particularly fruitful has been evaluation of dynamics effects in bearings that take into account the orbit of the shaft, along with simultaneous solutions of the energy equation taking lubricant property variations into consideration.

**Rolling Element Bearings**

Several isolated examples have been recorded of application of rollers in 484–424 BC for transporting vessels on land and for launching military missiles. While historical sources increasingly mention the use of balls and rollers for bearing purposes following about AD 1500, widespread application of rolling contact bearings occurred during the twentieth century (see especially Allan, 1945).

1780 Perhaps the earliest ball bearing: a 610 mm bore bearing was developed for a rotating mill in Norwich, UK.
1868 General use of ball bearings in bicycles began.
1899 Timken began the manufacture of tapered roller bearings.
1902 Conrad obtained a British patent for the present design of the deep-groove ball bearing with its cage.
1904 Ball and roller bearings were used in electric automobiles.
1907 SKF founded.
1949 Grubin established the elastohydrodynamic principles involved in the lubrication of rolling contacts.

Recent research has been geared toward understanding the relationship between surface topography (Chapter 3), film thickness, and pressure distribution in rolling element bearings. Under highly loaded conditions, when surface asperities tend to interact, a mixed-film lubrication regime may have to be considered. Prediction of subsurface stress fields and their relationship to fatigue are also subjects of current research.

**Nanotribology and Surface Effects**

Atomic-scale studies have been expanding rapidly to develop new materials with improved tribological properties. With an atom being approximately 1/3 nanometer (nm) in diameter,

Krim in 1991 initiated naming this field ‘nanotribology’ to parallel the broad field of ‘nanotechnology’ (Krim, 1991; Cantor, 2004). The nanometer (10^{-12} m, or 10 ångstroms) then provides a convenient scale for atomic and molecular sizes such as those in Table 1.1.

An early definition of atomic surface compositions that produces satisfactory sliding characteristics was provided in General Motors rubbing tests of all available metallic elements on steel (Roach et al., 1956). As detailed in Chapter 4, good scoring resistance was found only with elements that had atomic diameters at least 15% greater than iron and that were in the B subgroup of the periodic table, implying lack of tenacious metallic bonds at any localized junctions with steel.

Bushan (1997, 1999) updated the consideration of atomic structure and the related surface and lubricant details for avoiding wear under demanding operation with 0.15–0.3 nm thick air films in magnetic storage and micromechanical devices such as those involved in computer systems. Analysis of related air film bearings is provided in Chapter 11.

1.2 Tribology Principles

Several distinct regimes are commonly employed to describe the fundamental principles of tribology. These range from dry sliding to complete separation of two moving surfaces by fluid-film lubrication, with an intermediate range involving partial separation in boundary or mixed lubrication. When elastic surface deformation exerts a strong influence on fluid-film behavior, as in ball and roller bearings, elastohydrodynamic lubrication (EHL) introduces its distinctive characteristics.

**Dry Sliding**

In the absence of a fluid film, actual contact between two rubbing surfaces involves only sufficient high spots, or asperities, of the softer material so that their yield pressure balances the total load (Rabinowicz, 1995). Under load W in Figure 1.1, the real contact area is a relatively
minute portion of the apparent total area and tends to increase proportionately with the load (see Chapter 4).

A measurable force is required to slide a surface along on the contacting asperities (surface peaks) of another surface. This force must overcome the friction force associated with asperity yield strength. As suggested in Figure 1.1, friction can be significantly reduced by a thin, soft coating of a solid film lubricant such as graphite, molybdenum disulfide, or PTFE plastic, or by a sulfur- or phosphorus-rich layer formed by adsorption of additives from a lubricating oil. Wear volume can be related to the generation of wear fragments from a portion of these asperity contacts during sliding (see Chapters 2–4).

**Fluid-Film Lubrication**

In this regime, the moving surfaces are completely separated by a film of liquid or gaseous lubricant. A load-supporting pressure is commonly generated by one of the following types of action:

1. *Hydrodynamic lubrication (HL)* results from a film of separating fluid being drawn into a converging, wedge-shaped zone (as in Figure 1.2a) by the self-acting pumping action of a moving surface (Booser, 1995). Both the pressure and the frictional power loss in this film are a function of the lubricant’s viscosity in combination with the geometry and shear rate imposed by bearing operating conditions (see Chapter 5). Hydrodynamic bearings are commonly in the form of either (a) a *sleeve bearing* (also called a *journal bearing*) surrounding its mating journal surface on the shaft of a machine as a radial bearing or (b) a *thrust bearing* to provide an oil film at the face of a shaft shoulder or collar for location and axial support of a rotor.
2. *The squeeze-film action* shown in Figure 1.2(b) is encountered in dynamically loaded bearings in reciprocating engines and under shock loads (see Chapter 9). Because time is required to squeeze the lubricant film out of a bearing, much higher loads can be carried
in sleeve bearings for automotive engines and metal rolling mills than with a steady, unidirectional load, as reflected in the typical values presented in Table 1.2. The much lower load capacity of bearings lubricated with low-viscosity fluids such as water and air is also indicated in Table 1.2.

3. *Externally pressurized* feed by an external pumping source may be used to generate pressure in the fluid before its introduction into the bearing film, as shown in Figure 1.2(c). Such a procedure is common in cases where limited hydrodynamic pumping action is available within the bearing itself, as during starting and slow-speed running with heavy machines or with low-viscosity fluids (see Chapter 10).

Elastohydrodynamic Lubrication (EHL)

This is a form of hydrodynamic lubrication in which pressures are large enough to cause significant elastic deformation of the lubricated surfaces. As with HL, converging film thickness, sliding motion, and fluid viscosity play an essential role. Temperature effects, inadequate lubricant supply to the EHL film, and boundary lubrication play roles of varying importance, much as with fluid films in HL.

Significant differences between HL and EHL involve the added importance of material hardness, viscosity increase under high pressure, and degree of geometric conformation of the contacting surfaces. Conformal surfaces match snugly, such as the journal in a sleeve bearing with hydrodynamic lubrication shown in Figure 1.2, so that the load is carried on a relatively large area. With nonconformal surfaces, as with the two contacting rollers in Figure 1.3, the load must be carried on a small area: typically of the order of 1000-fold smaller than with a

![Figure 1.3](#)  Pressure distribution between two rollers under load.
conformal conjunction. The following two distinct regimes exist in EHL:

1. **Hard EHL.** This involves materials of high elastic modulus in nonconformal contacts, commonly contacts involving primarily rolling action or combined rolling and sliding in ball and roller bearings, gear teeth, cams, and some friction drives. Since the surfaces do not conform well, the load is concentrated on small, elastically deformed areas, and hydrodynamic lubrication of these EHL contacts is commonly characterized by a very thin separating oil film that supports local stresses that tax the fatigue strength of the strongest steels.

   Oil-film pressures in these EHL contacts commonly range up to 0.5–3 GPa, 1000 times that in most hydrodynamic bearings, with a pattern which closely follows the Hertz elastic contact stress for a static contact, as illustrated in Figure 1.3. The overall oil-film thickness (often about 0.1–0.5 μm) is set primarily by oil viscosity, film shape, and velocity at the entry of the contact zone (see Chapter 15).

2. **Soft EHL.** Elastic deformation also plays an important role in film formation in rubber seals, tires, human joints, water-lubricated rubber bearings, and babbitt journal bearings under heavy loads and low speeds, as well as in similar applications of hydrodynamic bearings using soft bearing materials having low elastic modulus. Since the low contact pressures involved have a negligible effect on fluid viscosity in the conjunction, analytical relations are simpler for soft EHL in contrast to the hard EHL encountered with rolling element bearings. Hamrock (1994) and Khonsari and Hua (1997) give analytical tools for performance analysis within the various realms of EHL.

**Boundary Lubrication**

As the severity of operation increases, the speed $N$ and viscosity $\mu$ eventually become incapable of generating sufficient oil-film pressure $P$ to support the entire load. Asperities of the mating surfaces then penetrate with increasing contact area, plastic deformation, higher asperity temperatures, and finally surface tearing and seizure on a broad scale. The region of lubrication in Figure 1.4 shifts from full film with a friction coefficient (ratio of friction force to

normal force) of the order of 0.001 to boundary (or mixed-film) lubrication, where the friction coefficient rises to 0.03–0.1, and finally to complete loss of film support, where the friction coefficient may reach 0.2–0.4, typical for dry sliding.

When operating with an adsorbed surface layer or a chemical reaction coating in boundary lubrication, chemical additives in the oil and chemical, metallurgical, and mechanical factors involving the two rubbing surfaces determine the extent of wear and the degree of friction.

1.3 Principles for Selection of Bearing Types

Most bearings can be classified as either fluid-film bearings, dry or semilubricated sliding bearings, or rolling element bearings (Khonsari and Booser, 2004). Their relative advantages are listed in Table 1.3. A general preliminary guide to selection of each of these types for different load, speed, and size relations is provided in Figure 1.5.

Example 1.1 A radial load of 500 N (112 lb) is to be carried by a bearing on a 25 mm (0.98 in.) diameter shaft. Which bearing types could be considered for speeds of 100, 1000, 10 000, and 100 000 rpm?

Follow horizontally across Figure 1.5 for a ‘Typical maximum load’ of 500 N. Speed and load limits are then found to be adequate for the following bearing types:
